Summary
For modeling discrete particle-block systems, a new framework of discontinuous deformation analysis is established on the basis of finite-dimensional variational inequality. The presented method takes into account the contacts, the rolling resistance, and the tensile resistance of cemented interface among particles and blocks using the corresponding variational or quasivariational inequalities. The new formulation avoids using the artificial springs that are usually indispensable in many conventional methods dealing with similar discrete problems and conveniently integrates the rigid circle particles, the nonrigid ring particles, and the arbitrary shape blocks into a uniform framework. The proposed discontinuous deformation analysis approach is further coupled with the finite element method using a node-based composite contact matrix and several simple transformation matrices to solve practical problems. A particle/block-based composite contact matrix is constructed to further broaden the application of the proposed method. The accuracy, robustness, and capability of the presented method are demonstrated with examples.

KEYWORDS
contact nonlinearity, discontinuous deformation analysis, projection-contraction algorithm, rolling resistance, variational inequality

1 INTRODUCTION

Discrete particle or block systems are commonly encountered in various engineering problems in civil, mechanical and chemical engineering, and mining industry. The mechanical responses in such systems are widely regarded complicated and challenging to characterize and model. They may include not only multibody interactions but also fluid-solid coupling and sometimes cross-scale interactions as well. Historically, there have been a wide variety of theories developed for analyzing such discrete particle/block systems, including fluid dynamics, granular mechanics, soil mechanics, rock mechanics, and powder technology. Indeed, discrete systems can range from very small to large length scales and can be tackled by different approaches. For example, the molecular dynamics method\textsuperscript{1-6} has been proposed to model the physical movements and interactions of atoms and molecules. The lattice Boltzmann method\textsuperscript{7-11} has been widely employed to simulate the evolution of a fluid system through modeling the collisions and propagations of fictive particles over a discrete lattice mesh. Meanwhile, the discrete element method (DEM)\textsuperscript{12-16} has been particularly popular in simulating engineering materials such as granular sands. The DEM typically treats a material as an assembly of discrete particles interacting with one another through interparticle contacts and frictions and solve the Newton’s equations of motion governing the
In this study, first, considering the independence between the shape of block and the basic unknowns in DDA, we extend the interpolation shape function of the circle particle to ring particle. In doing so, the rigid and nonrigid circles or ring particle, the arbitrary shape rigid and nonrigid block can all be integrated together to construct a new DDA framework. Moreover, the tactics of “double contact displacement” is proposed to overcome the aforementioned unphysical phenomenon of “one-step lag.” Second, applying the concept of instantaneous center of rotation in theoretical mechanics, the rolling resistance is translated into an equivalent variational inequality formulation. Meanwhile, the mechanical behavior of cemented interface is described by the quasivariational inequality and the normal and shear contacts. Consequently, the artificial springs can be totally abandoned in cases of normal contact, shear contact, rolling resistance, and tensile resistance of cemented interface. For simplicity, the new DDA framework will be abbreviated as particle-block (PB)–DDA in the sequel to highlight its capability of simulating complicated particle-block systems. Third, to accommodate cases where the particle or block needs to be further discreted, a node-based composite contact matrix is formulated to facilitate effective coupling between DDA and FEM, and meanwhile, it may help improve the accuracy of stress and strain of individual particle or block. Indeed, the DDA and the FEM share a common basis of the principle of minimum potential energy, which inspires us to introduce the FEM formula governing link/bolt, spring, and beam element directly into the PB-DDA. Therefore, the link/bolt, spring, and beam become the connectors between particles or blocks. To simulate the behavior of these connectors, thereafter, we construct a particle/block-based composite contact matrix, which allows other models to be implemented in the PB-DDA with ease, including the bonded particle model.
clumped particle model,\textsuperscript{39} and the bonded block model.\textsuperscript{40} The aforementioned enrichments greatly broaden the potential applications of the PB-DDA, which will be demonstrated with examples in the following sections.

2 | DISPLACEMENT APPROXIMATION

Consider a 2D rigid body with an arbitrary geometrical shape, as shown in Figure 1. The displacement of an arbitrary point A in the body can be described by its rotation about a certain axis passing through a reference point C and the translation of the body. The basic unknown vector is assumed as follows:

\[ \mathbf{d} = [u_0, v_0, \theta]^T, \]  

where \( u_0 \) and \( v_0 \) are the translational displacement of reference point of a particle or block in the \( x \) and \( y \) direction, respectively. \( \theta \) is the rotation angle of the rigid body about the axis passing through the reference point C, which is assumed to be the geometric centroid of a particle or block in this study. The displacement \( \mathbf{u}(x, y) \) of any point A can be expressed as

\[ \mathbf{u}(x, y) = \begin{bmatrix} u_x(x, y) \\ u_y(x, y) \end{bmatrix} = \mathbf{T}(x, y)\mathbf{d}, \]  

where \((x, y)\) is the coordinate of point A and the interpolation shape function \( \mathbf{T}(x, y) \) is given by

\[ \mathbf{T}(x, y) = \begin{bmatrix} 1 & 0 & y - y_c \\ 0 & 1 & x - x_c \end{bmatrix}, \]  

where \((x_c, y_c)\) is the coordinate of point C. In the framework of DDA, a rigid body with complex geometry can be presented straightforward with its shape features, without resorting to the use of many particles to approximate its profile in other approaches such as DEM.

Now, we further consider a particle or a ring-shaped body (which can be regarded as a particle with a nonzero inner diameter), which can only exhibit volumetric deformation without shear strain. The following basic unknown vector can be adopted:

\[ \mathbf{d} = [u_0, v_0, \theta, \varepsilon_x]^T, \]  

where \( \varepsilon \) is the Cauchy strain and \( \varepsilon_x = \varepsilon_y = \varepsilon \) in this case. Accordingly, the interpolation shape function can be expressed

\[ \mathbf{T}(x, y) = \begin{bmatrix} 1 & 0 & y - y_c & x - x_c \\ 0 & 1 & x - x_c & y - y_c \end{bmatrix}. \]  

For a deformable block of arbitrary shape, the basic unknown vector can be written as

\[ \mathbf{d} = [u_0, v_0, \theta, \varepsilon_x, \varepsilon_y, \gamma_{xy}]^T, \]  

where \( \varepsilon_x, \varepsilon_y, \) and \( \gamma_{xy} \) are the 3 Cauchy strain components. The corresponding interpolation shape function is

\[ \mathbf{T}(x, y) = \begin{bmatrix} 1 & 0 & y_c - y & x - x_c & 0 & \frac{y - y_c}{x - x_c} \\ 0 & 1 & x_c & (y - y_c) & 0 & \frac{x - x_c}{x - x_c} \end{bmatrix}. \]  

FIGURE 1  Geometrical shapes of rigid or deformable body [Colour figure can be viewed at wileyonlinelibrary.com]
The interpolation functions in Equations (3), (5), or (7) are all first-order functions of $x$ and $y$. The interpolation shape function and the basic unknown vector constitute the bases for establishing the control equation of motion of a body.

3 CONTACT TYPES

Major contact types considered in our method include, but not limited to, the particle-particle contact (P–P contact), the particle-block contact (P-B contact), the block-block contact (B-B contact), and the loop–loop contact (L-L contact), each of which is discussed as follows.

For particle-particle contacts, we consider the following 2 cases. Case I occurs when 2 particles are considered “outside” to each other (e.g., Figure 2A); Case II occurs when particle $P_i$ is inside of particle $P_j$ whose inner diameter is nonzero, as shown in Figure 2B. The centroid line $P_iP_j$ intersects particles $P_i$ and $P_j$ at points $C_i$ and $C_j$, respectively, where $i$ and $j$ are the global indexes of the 2 particles. If the distance between $C_i$ and $C_j$ is less than a specified threshold $d_0$, particles $P_i$ and $P_j$ are considered to be in contact, and this contact can marked as contact pair $C_i$-$C_j$-PP, where the subscript “PP” indicates that the contact is a particle-particle contact. The midpoint of points $C_i$ and $C_j$ is defined as the contact point $C$. Line $AB$ passes through the contact point $C$ and is perpendicular to line $P_iP_j$. It is defined as the contact surface. The unit vector $n$ from point $C$ to point $P_i$ is defined as the unit normal vector of the contact pair. For convenience in programming, we take the index $i$ is less than the index $j$, namely, $i < j$. Thus, the unit vector $n$ points toward the interior of particle with the smaller index. The unit shear vector $\tau$ of the same contact pair is defined by rotating $n$ clockwise, as shown in Figure 2.

For particle-block contacts, 4 cases, as shown in Figure 3, are considered. Case I: Particle $P_i$ contacts the edge $V_iV_j$ of block $B_j$ from the outside of the block (see Figure 3A); Case II: Particle $P_i$ contacts block $B_j$ from the inside of the block (see Figure 3B); Cases III and IV: The vertex $V_j$ of block $B_j$ contacts particle $P_i$ from either the outside of inside of the particle, as shown in Figure 3C and 3D, respectively. In cases I and II, if the distance $C_iC_j$ is less than a specified threshold $d_0$, these contacts will occur and are termed as $C_iV_iV_j$-PB, where the subscript “PB” denotes a particle-block contact. The midpoint of line $C_i$ and $C_j$ is defined as the contact point $C$, and line $DE$ paralleling to edge $V_iV_j$ and passing through point $C$ is defined as the contact surface, as shown in Figure 3A and 3B. For cases III and IV, if the distance between point $C_i$ and vertex $V_j$ is less than $d_0$, such a contact will occur and is termed as $C_jV_j$-PB. The contact surface $DE$ is perpendicular to line $P_iV_j$ and passes through the contact point $C$ defined by the midpoint of line $C_iV_j$, as shown in Figure 3C and 3D. The unit normal vector $n$ is perpendicular to line $DE$ and points to the interior of particle $P_i$. By rotating $n$ clockwise, we can obtain the unit shear vector $\tau$, as shown in Figure 3.

Three contact types between blocks are considered in the original DDA, namely, the vertex-edge contact, the edge-edge contact, and the vertex-vertex contact. Among the 3, the vertex-edge contact is considered the most basic one, while the latter 2 types can be ultimately translated into the vertex-edge contact, as shown in Figure 4. Point $V^*$ is the projection of vertex $V_k$ belonging to block $B_i$ on edge $V_iV_j$ of block $B_j$. If the distance between points $V_k$ and $V^*$ is less than $d_0$,
the contact pair $V_k-V_l$-$BB$ is detected, where the subscript “BB” stands for the block-block contact. The midpoint of line $V_kV^*$ is defined as the contact point C. It should be pointed out that vertexes $V_k$ and $V^*$ are the 2 contact points belonging to blocks $B_i$ and $B_j$, respectively, in the original DDA, and vertex $V_k$ and vertex $V^*$ are thereby considered separate points. In reality, once contacted, the contact point can be regarded as 1 single point for the 2 contact bodies. In this study, midpoint C is defined as the contact point. Indeed, blocks $B_i$ and $B_j$ may own contact point C simultaneously, which has been validated by numerical simulations. The contact surface $DE$ is parallel to edge $V_iV_j$ and passing through point C. The unit normal vector $n$ is perpendicular to line $DE$ and points to the interior of block $B_j$, which possesses edge $V_iV_j$. By rotating $n$ clockwise, the unit shear vector $\tau$ can be obtained, as shown in Figure 4.

Figure 5 shows the edge-edge contact. If the distances between vertexes $V_k$, $V_l$, and edge $V_iV_j$ are all less than $d_0$ (the left of Figure 5) or the distances between vertexes $V_k$ and $V_l$ and edges $V_iV_j$ and $V_kV_l$ are all less than $d_0$ (the right of Figure 5), the edge-edge contact $V_kV_l$-$V_iV_j$-$BB$ is considered to occur, and it is further translated into 2 pair of vertex-edge contacts, namely, the vertex-edge contacts $V_k$-$V_i$-$V_j$-$BB$ and $V_j$-$V_i$-$V_l$-$BB$ (the left of Figure 5) or the vertex-edge contacts $V_k$-$V_i$-$V_j$-$BB$ and
V_i-V_k V_{fBB} (the right of Figure 5). In this case, one of the contact pairs is called as the “adjoint contact pair” of the other contact pair. The vertex-edge contact V_k-V_i V_{fBB} or V_i-V_k V_{fBB}, is called “adjoint vertex-edge contact”.

As for the vertex-vertex contact, one needs first to identify the 2 candidate contact edges and then to select 1 edge and 1 vertex according to the geometrical relationship to form a vertex-edge contact. Accordingly, the treatment of vertex-vertex hereby adopted is the same as the way in the original DDA.

To account for deformability, a block can be subdivided into elements. In this case, the boundary of the block is called the loop, as shown in Figure 6. Both blocks B_i and B_j are subdivided. If there is a contact between the 2 blocks, the contact is referred to as the loop-loop contact (L-L contact). Since elements E_{ik} and E_{jk} can be regarded as 2 smaller blocks, the loop-loop contact can be treated as a block-block contact. Apparently, depending on different circumstances, there may be particle-loop contacts (P-L contacts) and block-loop contacts (B-L contacts) in a discrete particle-block system, as shown in Figure 7. The former can be treated as the particle-block contacts, while the latter can be tackled as the block-block contacts.

FIGURE 7  Particle-loop contact and block-loop contact [Colour figure can be viewed at wileyonlinelibrary.com]
Variational inequality has been employed in treating the Signorini problem,\textsuperscript{41} and its application in DDA can be found in the work of Jiang and Zheng,\textsuperscript{40} while detailed theory about variational inequality can be referred to the work of Facchinei and Pang\textsuperscript{42}. Here, we will offer the equivalent formulations of the contact conditions, the rolling resistance, and the tension resistance of the cemented interface under the framework of the variational inequality. For completeness, the governing equation of a single body (particle or block) motion is briefly discussed.

### 4.1 Governing equation of a body motion

Consider a rigid or deformable block $B_i$, as shown in Figure 8. The centroid of the block is located at point $C$. In this Figure, $G$ denotes the body force; $F$, $P$, and $u$ are the specified point loading, surface loading, and displacement constraint, respectively. The vertices $V_k$ and $V_m$ are the contact points and the unit vectors $n_k$, $\tau_k$, and $n_m$, $\tau_m$ corresponds to the $k$th and the $m$th contact pairs, respectively. According to the definitions for the unit normal and shear vector and the laws of action and reaction, the contact force ($p'_k n_k$, $p'_k \tau_k$) acts on edge $VV_k$ of block $B_k$, while the contact force ($-p'_m n_m$, $-p'_m \tau_m$) applies to vertex $V_m$ of block $B_m$. We consider a block $B_i$ with $n_i$ contact pairs.

The Newmark scheme\textsuperscript{63} with adopted parameters $\gamma = 1.0$ and $\beta = 0.5$ is employed in the time integration of this study. In consideration of the interpolation shape function $T(x, y)$ and the minimization of total potential energy of the block, the governing equation for a body motion can be expressed as\textsuperscript{50}

$$K_i d_i - C_ip_i = f_i, \quad \text{Eq. (8)}$$

where $K_i$ is the equivalent stiffness matrix, $d_i$ is the basic unknown vector, and $f_i$ is the equivalent loading vector. $C_i$ and $p_i$ are the contact matrix and the undetermined contact force vector acting on block $B_i$, respectively. Note that the dimensions of Equation (8) can be 3, 4, or 6 for the rigid particle or block, the deformable particle, or the deformable block, respectively. For a rigid or deformable particle, the Appendix summarizes the analysis formulas of key submatrices needed for the generation of $K_i$; while for a rigid or deformable block, the simplex integration method\textsuperscript{52} is adopted.

The contact matrix is given by

$$C_i = \begin{bmatrix} C_i^1, C_i^2, \ldots, C_i^k, \ldots, C_i^{n_i} \end{bmatrix}, \quad \text{Eq. (9)}$$

where each $C_i^k$ is the $3 \times 2$, $4 \times 2$, or $6 \times 2$ matrix associated with the $k$th contact pair on block $B_i$ defined as follows:

$$C_i^k(x_k, y_k) = s_k T_i^k(x_k, y_k) [n_k, \tau_k], \quad k = 1, \ldots, n_i, \quad \text{Eq. (10)}$$

where $(x_k, y_k)$ are the coordinates of the $k$th contact point and $s_k$ is the sign indicating that the $k$th contact force is either positive or negative according to the definition of the unit normal and shear vector. In addition, the $2 \times 2$ matrix $[n_k, \tau_k]$ is expressed as

$$[n_k, \tau_k] = \begin{bmatrix} \cos \alpha_k^n & \cos \alpha_k^\tau \\ \cos \beta_k^n & \cos \beta_k^\tau \end{bmatrix}, \quad \text{Eq. (11)}$$

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure8.png}
\caption{Edge-edge contacts of the block-block contact [Colour figure can be viewed at wileyonlinelibrary.com]}
\end{figure}
where \((\cos \alpha \beta_k, \cos \beta_n)\) and \((\cos \alpha_k, \cos \beta_k)\) are the direction cosines of the vectors \(\mathbf{n}_k\) and \(\mathbf{r}_k\), respectively. The contact force vector \(\mathbf{p}_i\) for the \(n_i\) contact pairs on block \(B_i\) is

\[
\mathbf{p}_i = [p_{i1}^n, p_{i1}^r, p_{i2}^n, p_{i2}^r, \ldots, p_{in}^n, p_{in}^r]^T. \tag{12}
\]

If the action point of a point loading does not coincide with the centroid of a body, the point loading may result in both body translation and rotation. For a rigid body, the following interpolation shape function can be used to translate the point load into an equivalent loading vector:

\[
\mathbf{T}^R(x, y) = \begin{bmatrix} 0 & 0 & y_c - y \\ 0 & 0 & x - x_c \end{bmatrix}, \tag{13}
\]

such that the point loading will only cause the rotation of the rigid body. As illustrated in Figure 9, the use of \(\mathbf{T}^R(x, y)\) renders the effect of loading \(\mathbf{F}\) applied at point \(A(x, y)\) to be equivalent to the moment \(\mathbf{m}^R\) acting on the centroid \(C(x_c, y_c)\). Indeed, \(\mathbf{T}^R(x, y)\) will also be employed in the implementation of the rolling resistance.

Note that, for a deformable particle, \(\mathbf{T}^R(x, y)\) becomes

\[
\mathbf{T}^R(x, y) = \begin{bmatrix} 0 & 0 & y_c - y \\ 0 & 0 & x - x_c \end{bmatrix}, \tag{14}
\]

while for a deformable block, \(\mathbf{T}^R(x, y)\) should be written as

\[
\mathbf{T}^R(x, y) = \begin{bmatrix} 0 & 0 & y_c - y \\ 0 & 0 & x - x_c \end{bmatrix}, \tag{15}
\]

It should be noted that the interpolation shape function \(\mathbf{T}(x, y)\) or \(\mathbf{T}^R(x, y)\) and the basic unknown vector \(\mathbf{d}\) are only used to construct the governing equation. To overcome the possible volume expansion caused by the rotation of rigid body, the postadjusted method will be employed to calculate the displacement of any point after solving the controlling equation. For a rigid particle or block, the postadjusted displacements are

\[
\begin{cases}
u_x = u_0 + (x - x_c) (\cos \theta - 1) - (y - y_c) \sin \theta \\v_y = v_0 + (x - x_c) \sin \theta + (y - y_c) (\cos \theta - 1),
\end{cases} \tag{16}
\]

while for a deformable particle,

\[
\begin{cases}
v_x = u_0 + (x - x_c) (\cos \theta - 1) - (y - y_c) \sin \theta + (x - x_c) \v_x \\v_y = v_0 + (x - x_c) \sin \theta + (y - y_c) (\cos \theta - 1) + (y - y_c) \v_y,
\end{cases} \tag{17}
\]

and for the deformable block, \(^{14}\)

\[
\begin{cases}
u_x = u_0 + (x - x_c) (\cos \theta - 1) - (y - y_c) \sin \theta + (x - x_c) \v_x + (y - y_c) \v_{xy}/2 \\v_y = v_0 + (x - x_c) \sin \theta + (y - y_c) (\cos \theta - 1) + (y - y_c) \v_y + (x - x_c) \v_{xy}/2.
\end{cases} \tag{18}
\]

**FIGURE 9** Equivalent moment caused by a point loading [Colour figure can be viewed at wileyonlinelibrary.com]
4.2 | Contact force

Frictional resistance will be triggered when there is either a trend of relative sliding or a real relative sliding occurring along the contact surface defined previously, according to the static friction and the sliding friction, respectively. For a typical vertex-edge contact pair $k$, if the following shear strength is adopted:

$$\tau \left( p^n_k \right) = c_k + \mu_k p^n_k,$$

where $p^n_k$ is the normal contact force of the $k$th contact pair, $c_k$ is the cohesion of the contact surface, and $\mu_k$ is the sliding friction coefficient. Equation (19) is a function of $p^n_k$. Considering the Coulomb friction law, the friction-induced shear contact force $p^c_k$ should fall in the interval of $[-\tau(p^n_k), \tau(p^n_k)]$. In other words, the shear contact force $p^c_k$ is a function of the normal contact force $p^n_k$. On the other hand, because the contact force vector $p_i$ in Equation (8) is undetermined, in order to obtain the basic unknown vector $d_i$ in Equation (8), $d_i$ can be split into the following 2 components:

$$d_i = d'_i + d''_i.$$

where $d'_i$ and $d''_i$ are the contributions of the contact force vector $p_i$ and the equivalent loading vector $f_i$, respectively. As a result, Equation (8) can be further rewritten as

$$\mathbf{K}d'_i = f_i,$$

and

$$\mathbf{K}d''_i = \mathbf{C}p_i.$$  \hspace{1cm} (22)

Indeed, the partition expressed by Equation (20) embodies the idea of “predictor-corrector” technique as follows. A “predicted value” is first obtained without considering the contact force, and a “corrected value” is then calculated when the contact force is considered, which is further added to the “predicted value.” As a matter of convenience, Equations (21) and (22) are referred to as “noncontact step” and “contact step,” respectively. From Equations (21) and (22), we can readily calculate

$$d'_i = \mathbf{K}^{-1}f_i,$$

$$d''_i = \mathbf{K}^{-1}\mathbf{C}p_i.$$  \hspace{1cm} (24)

To determine $d''_i$, one needs to solve the contact force vector $p_i$ first. According to the work of Zheng et al., the constraints of no-penetration constraint and no-tension constraint at the contact point can be translated into the following complementarity condition:

$$\begin{cases}
g_k^n \geq 0, & p_k^n \geq 0 \\
g_k^c p_k^n = 0,
\end{cases}$$

which is equivalent to the variational inequality VI-$p^*(k)$. Find $p_k^n \geq 0$ such that

$$(q_k^c - p_k^n) g_k^c \geq 0, \quad \forall q_k^n \geq 0,$$

where $q_k^n$ is related to the normal contact force $p_k^n$ and $g_k^c$ is the normal contact gap of the $k$th contact pair. Moreover, the Coulomb friction law can be reformulated into the following condition:

$$\begin{cases}
g_k^c \geq 0, & \text{if } p_k^c = -\tau(p_k^n) \\
g_k^c = 0, & \text{if } |p_k^c| < \tau(p_k^n) \\
g_k^c \leq 0, & \text{if } p_k^c = \tau(p_k^n),
\end{cases}$$

where $g_k^c$ is the tangential relative sliding gap of the $k$th contact pair and $\tau(p_k^n)$ is determined by Equation (19). Furthermore, the condition Equation (27) is equivalent to the quasivariational inequality QVI-$p^*(k)$. Find $|p_k^c| \leq \tau(p_k^n)$ such that

$$(q_k^c - p_k^n) g_k^c \geq 0, \quad \forall |q_k^n| \leq \tau(p_k^n).$$

In the following, we will redefine the gaps $g_k^n$ and $g_k^c$. For a typical $k$th vertex-edge contact pair shown in Figure 10, at the starting time $t_0$ of the current time step, the contact point $V_k^i(x^n_i, y^n_i)$ belonging to block B coincides with the contact point $V_k^i(x^p_i, y^p_i)$ that belongs to block B. At the end of the time step $t_0 + \Delta t$, the contact points $V_k^i$ and $V_k^i$ move to $V_k^i(x_i, y_i)$
and $V_k^r(x_j, y_j)$, respectively. The normal contact gap $g_k^n$ is the projection of the vector $R_k$ pointing $C_k^r$ to $C_k^r$ onto $n_k$, according to

$$ g_k^n = n_k^T(x_j - x_i), $$

where

$$ x_m = [x_m, y_m]^T = [x_m^0, y_m^0]^T + T_m (x_m^0, y_m^0) \left( d_m^i + d_m^f \right), \quad m = i, j. $$

After some mathematical manipulations, we have

$$ g_k^n = p_{ij}^n + g_{ij}^n, $$

where

$$ p_{ij}^n = n_j^T p_i - n_i^T p_j $$

and

$$ n_{ki}^T = n_k^T T_i F_i $$

and

$$ n_{ki}^T = n_k^T T_j F_j, $$

where $C_m(m = i, j)$ is the contact matrix (Equation (9)). Note that $x_j^0 - x_i^0 = 0$ at the start of the current time step; Equation (34) is reduced to

$$ g_{ij}^n = n_k^T \left( T_i d_j^f - T_j d_i^f \right). $$

In the tangential direction, the tangential relative sliding gap $g_k^\tau$ is defined as

$$ g_k^\tau = \tau_k^T (u_j - u_i), $$

where

$$ u_m = [u_m^x, u_m^y]^T = T_m (x_m^0, y_m^0) \left( d_m^i + d_m^f \right), \quad m = i, j. $$

Similar to $g_k^n$, we have

$$ p_{ij}^\tau = \tau_j^T p_i - \tau_i^T p_j $$

and

$$ \tau_{ki}^T = \tau_k^T T_i F_i $$

and

$$ \tau_{kj}^T = \tau_k^T T_j F_j, $$

where $R_k$ pointing $C_k^r$ is called the flexibility matrix.
If there are $N$ contact pairs in a discrete particle-block system at the current time step, each contact pair corresponds to the variational inequality VI-$p^n$ and the quasivariational inequality QVI-$p^\tau$. By combining all of these VI-$p^n$ and QVI-$p^\tau$, we have the following dual form of DDA, abbreviated as DDA-d.\cite{56} Find the global contact force vector $p \in X(p) \subset \mathbb{R}^{2N}$ such that

$$ (q - p)^T G(p) \geq 0, \quad \forall q \in X(p), $$

where

$$ p = [p_1^n, p_1^\tau, \ldots, p_N^n, p_N^\tau]^T, $$

and the constraint $X(p)$ is a closed set in $\mathbb{R}^{2N}$ and dependents on the global contact force vector $p$. In addition, the contact gap function $G(p)$ is defined as

$$ G(p) = [g_1^n(p), g_1^\tau(p), \ldots, g_N^n(p), g_N^\tau(p)]^T. $$

One can refer to the work of Zheng et al.\cite{56} for more detail. In this study, the compatibility iteration\cite{56} based on the projection-contraction algorithm\cite{64} will be adopted, which, in conjunction with the variational or quasivariational inequality formulations, can help totally avoid using the artificial contact spring, and may replace the OCI of the original DDA to solve all the contact forces occurring in a discrete particle-block system.

In addition, note that the shear strength described by Equation (19) is no longer suitable for the adjoint vertex-edge contact, which stems from a same edge-edge contact when the cohesion $c$ is nonzero. The shear strength for the adjoint vertex-edge contact needs to be reexamined specifically. As shown in Figure 11, vertex-edge contacts $V_1$-$V_3V_4$ and $V_2$-$V_3V_4$ are 2 adjoint vertex-edge contact pairs, which should join together to resist the potential tangential sliding. It has been reported that there is an unreasonable sharing ratio\cite{65} between them in the OCI of the original DDA. This unreasonable ratio may cause that the 2 contact pairs cannot undergo the state of opening, sliding, or closing at the same time. If the cohesion $c \neq 0$, we might rewrite $c$ as follows:

$$ c = c_1 + c_2, $$

where $c_1$ and $c_2$ correspond to the contributions by contacts $V_1$-$V_3V_4$ and $V_2$-$V_3V_4$, respectively, and satisfy

$$ k_c \equiv \frac{c_1}{c_2} = 1, $$

and thus, for the contact $V_1$-$V_3V_4$, the shear strength can be given by

$$ \tau (p_1^n) = \frac{k_c}{1 + k_c} c + \mu_1 p_1^n, $$

and for the contact $V_2$-$V_3V_4$, the shear strength reads

$$ \tau (p_2^n) = \frac{1}{1 + k_c} c + \mu_2 p_2^n. $$

At the end of the compatibility iteration,\cite{56} $k_c$ will converge to an appropriate value, leading naturally to a final unique compatible contact state for the 2 adjoint vertex-edge contact pairs.
Once the compatibility iteration is completed, the contact conditions of no penetration and no tension at the contact points are expected to be satisfied. More specifically, the normal gaps should all be equal to zero, and the shear gaps converge to correct values. However, according to our numerical experience, there are cases where an unphysical phenomenon of "one-step lag" may occur in the aforementioned "predictor-corrector" process, which needs to be fixed. To demonstrate this, the normal contact, as shown in Figure 12, is taken as an example.

Assume that there is a contact pair at the initial step (at time $t_0$), with point $C_0$ being the contact point (see Figure 12). During the noncontact step, namely, when the contact force is not considered, contact point $C_0$ reaches at point $C^*$, leading to an initial nonzero normal contact gap $g_{n0} \neq 0$. The compatibility iteration is then invoked until the convergence is achieved to determine the normal contact force. The determined contact force is further considered to carry out the contact step in an attempt to make $g_{n0} = 0$, equivalently, to push point $C^*$ back to point $C_1$ at time $t + \Delta t$. Now, the following phenomenon can be clearly pictured. After the time interval $\Delta t$, the position of the contact point remains at its initial position. Physically, the normal contact force should occur at the time when contact occurs, but the normal contact gap does not yet appear. In addition, the same applies to the shear direction. This phenomenon is the so-called “one-step lag”. If the initial velocity component of any block or particle is not equal to zero at the initial time $t$, to eliminate this undesired lag, the ultimate basic known at time $t + \Delta t$ is estimated by

$$\text{if } (v_i^0 \neq 0) \quad \ddot{d_i} = 2d_i^0 + d_i^f, \quad (i = 1, 2, \ldots, k),$$

where $k$ is equal to 3 for rigid body or 4 for deformable particle or 6 for deformable block. This is to say that the displacement caused by the contact force is doubled at $t + \Delta t$ time. Equation (46) is referred to as “double contact displacement” in this paper.

In the Newmark time integration, the velocity and acceleration are computed based on the basic knowns. Thus, the modified basic known $\ddot{d}$ (see Equation (46)) can be used to update the stress and the relevant geometry, while the original basic known $d$ (see Equation (20)) is still employed to calculate the velocity and acceleration. This is demonstrated in the following examples.

### 4.4 Rolling resistance for particles

Rolling resistance may become important for a particle-particle contact or a particle-block contact. An illustration of modeling of rolling resistance in this study is shown in Figure 13. There is a contact pair between particle $O_i$ (the centroid of the particle) and surface AB. Vectors $n$ and $\tau$ are the unit normal and shear vector, respectively. $G$ is the gravity force of the particle, and $F$ is the point loading acting on point A. While $p^n n$ is the normal contact force determined by the compatibility iteration, $\hat{p} \cdot \tau$ can be called the unknown rolling friction. $\omega_i$ is the initial angle velocity, $R$ is an undetermined distance, and $\delta$ is the rolling friction coefficient with a dimension of length.

The rolling resistance is intended both to limit the translational motion of the particle and to suppress its rotation. To this end, we consider the contact point C as a temporary fixed point inspired by the fact that the contact point C is the instantaneous center of rotation, which implies that the instantaneous velocity of point C is zero. We then move the normal contact force $p^n n$ by an undetermined distance $R$ on the contact surface AB; thus, we have a normal rolling resistance force $\hat{p} \cdot n$, as shown in Figure 13. An equivalent moment, referred to as the rolling resistance moment, can
then be constructed as follows:

\[ m^R s = \bar{\rho} n \times d^R \tau \]

\[ s = n \times \tau. \tag{47} \]

Suppose that there are \( n_R \) rolling resistant forces acting on the particle \( O_i \), by applying the interpolation shape function \( T^R(x, y) \) expressed by Equation (13), (14), or (15), the total applied moment \( m^R s \) can be translated into the equivalent loading vector for the governing equation

\[ \mathbf{R} \cdot \mathbf{m}^R s \rightarrow \mathbf{f}_i, \tag{48} \]

where

\[ \mathbf{m}^R = [m^R s_1, \ldots, m^R s_n]^T = [\bar{\rho} n_1 \times d^R \tau_1, \ldots, \bar{\rho} n_n \times d^R \tau_n]^T, \tag{49} \]

which is referred to as the rolling resistance moment vector, and

\[ \mathbf{R}_i = [T^R_1, \ldots, T^R_n]. \tag{50} \]

The matrix \( \mathbf{R}_i \) is called the rolling resistance matrix in this study. The exerted moment \( m^R s \) on the particle may lead to an additional contribution to the basic unknown vector as follows:

\[ d^R \rightarrow d_i, \]

where \( d^R_i \) is caused by the rolling resistance moment \( \mathbf{m}^R_i \). Since point \( C \) is assumed to be temporarily fixed, the displacement \( \mathbf{u}_O = (u_{ox}, u_{oy})^T \) of point \( O \) is maybe nonzero. According to Newton's second law, one has

\[ \bar{\rho} \tau = \frac{2M_{\text{ass}} \bar{d}^T}{(\Delta t)^2}, \tag{52} \]

where \( M_{\text{ass}} \) is the mass of the particle, \( \Delta t \) is the time step size, and \( \bar{d}^T \) is the tangential displacement of point \( O \) given by

\[ \bar{d}^T = \mathbf{u}^T \tau. \tag{53} \]

In practice, there is no need to consider the force \( \bar{\rho} \tau \) since its action point \( C \) has been temporarily fixed.

For an arbitrary \( k \)th rolling resistance, due to the moment \( m^R s \), the particle undergoes a rotation angle \( \theta_m \). Considering the initial angle velocity \( \omega_0 \) and the rotation angle \( \theta_f \) caused by external loads, we have the following total rotation angle:

\[ g_k^R (m^R s) = \omega_0 \Delta t + \theta_f + \theta_m. \tag{54} \]

In this study, \( g_k^R \) is called the rolling gap, taking counterclockwise as positive. In analogy to the shear strength, a “rolling strength” is defined as follows:

\[ \tau^R (d^R_k) = \bar{\rho} d^R_k \tag{55} \]

where \( d^R_k \) (see Figure 13) is undetermined. In analogy to the Coulomb friction law, one can have the following condition similar to Equation (27):

\[ g_k^R \begin{cases} \geq 0, & \text{if } m^R_k = -\tau^R (d^R_k) \\ = 0, & \text{if } |m^R_k| < \tau^R (d^R_k) \\ \leq 0, & \text{if } m^R_k = \tau^R (d^R_k). \end{cases} \tag{56} \]
Indeed, \( g_k^R \) and \( m_k^R \) can be seen as a pair complementary variable. Figure 14 depicts the relationship between them.

Consequently, we can further establish the following equivalent quasivariational inequality QVI-\( m_k^R \). Find \(|m_k^R| \leq r^R(d_k^R)\) such that

\[
(q_k^R - m_k^R) g_k^R \geq 0, \quad \forall q_k^R \leq r^R(d_k^R),
\]

which is a counterpart to Equation (28) in the rolling case.

If there are \( N \) rolling resistances in the discrete particle-block system at the current time step, there are \( N \) quasivariational inequalities QVI-\( m_k^R \). Assembling them leads to the following formulation for the rolling resistance. Find the global rolling resistance moment vector \( \mathbf{M}^R \in X(\mathbf{M}^R) \subset \mathbb{R}^N \) such that

\[
(q^R - \mathbf{M}^R)^T G(\mathbf{M}^R) \geq 0, \quad \forall q^R \in X(\mathbf{M}^R),
\]

where

\[
\mathbf{M}^R = [m_1^R, m_2^R, \ldots, m_N^R]^T,
\]

and the rolling gap function \( G(\mathbf{M}^R) \) reads

\[
G(\mathbf{M}^R) = [g_1^R(\mathbf{M}^R), \ldots, g_k^R(\mathbf{M}^R), \ldots, g_N^R(\mathbf{M}^R)]^T,
\]

where the rolling gap \( g_k^R(\mathbf{M}^R) \) is defined by Equation (54). Moreover, the constraint \( X(\mathbf{M}^R) \) is dependent on the \( \mathbf{M}^R \) and is a closed set in \( \mathbb{R}^N \) as follows:

\[
X(\mathbf{M}^R) = X_1(m_1^R) \times \cdots \times X_k(m_k^R) \times \cdots \times X_N(m_N^R),
\]

where \( X_k(m_k^R) \subset \mathbb{R} \) is the constraint set of the rolling resistance moment \( m_k^R \) in the \( k \)th rolling resistance and relies on the distance \( d_k^R \) associated with the \( k \)th rolling resistance. It is given by

\[
X_k(m_k^R) = \left\{ \left| m_k^R \right| \leq r^R(d_k^R) \right\} = [-r^R(d_k^R), r^R(d_k^R)],
\]

for \( k = 1, \ldots, N \), with \( r^R(d_k^R) \) defined by Equation (55).

### 4.5 Tensile resistance at cemented interface

Cementations may exist at natural or artificial interfaces or joints and may account for certain tensile strength at the interface or joint. Take the case in Figure 15 as example. Two blocks, connected by a joint \( k \), are subjected to 3 forces \( \mathbf{F}_1 \), \( \mathbf{F}_2 \), and \( \mathbf{F}_3 \) acting on points \( A_1 \), \( A_2 \), and \( A_3 \) respectively. The tensile resistance offered by the joint \( C_i^j/C_j^j \) is in an opposite direction to the interface tension \( -p_i^j \mathbf{n}_k \) and acting on point \( C_i^j \) of block \( B_i \), where the definition of \( \mathbf{n}_k \) is the same as Section 3. Assume that the allowable tensile deformation of the cementing material is \( d_i^{t_1} \). In other words, the interface tension \( -p_i^j \mathbf{n}_k \) will reach its maximum once the distance \( g_k^i \) between points \( C_i^j \) and \( C_j^j \) is equal to \( d_i^{t_1} \). Moreover, if the distance continues to be increased, the cementing material will be broken. According to

\[
g_k^i = \begin{cases} g_k^i - d_i^{t_1} = 0, & \text{if } p_i^j = 0 \\ g_k^i - d_i^{t_1} < 0, & \text{if } 0 \leq p_i^j \leq t_k, \end{cases}
\]

where \( t_k \) is the tensile strength of joint \( k \) and \( g_k^i \) is called the tensile gap. In this study, 4 hypotheses are adopted. (i) Only the cemented joints or interfaces detected at time \( t = 0 \) is needed to be considered. (ii) The cementing material is inextensible before failure, namely, \( d_i^{t_1} = 0 \), as illustrated in Figure 16. (iii) The external force does not effect on the tensile strength of cementing material before failure. (iv) The tensile strength of cementing material is unrecoverable after failure.
Furthermore, Equation (63) can be made equivalent to its variational inequality VI-$p^t(k)$. Find $0 \leq \tilde{u}^{t_1} \leq t_k$ such that

$$(q^t_k - p^t_k) g^t_k \geq 0, \quad \forall 0 \leq q^t_k \leq t_k.$$  

(64)

If there are $N$ joints in the discrete particle-block system at the current time step, there will be $N$ variational inequalities VI-$p^t$, which combine to form the following variational formulation for the tensile resistance at the interface. Find the global interface tension vector $p^t \in X(p^t) \subset \mathbb{R}^N$ such that

$$(q^t - p^t) G(p^t) \geq 0, \quad \forall q^t \in X(p^t),$$  

(65)

where

$$p^t = [p^t_1, p^t_2, \ldots, p^t_N]^T.$$  

(66)

and the tensile gap function $G(p^t)$ is given by

$$G(p^t) = [g^t_1(p^t), \ldots, g^t_k(p^t), \ldots, g^t_N(p^t)]^T,$$  

(67)

where $g^t_k(p^t)$ is the tensile gap. In addition, the constraint $X(p^t)$ depending on the $p^t$ is a closed set in $\mathbb{R}^N$ and is defined by

$$X(p^t) = X_1(p^t_1) \times \cdots \times X_k(p^t_k) \times \cdots \times X_N(p^t_N),$$  

(68)

where $X_k(p^t_k) \subset \mathbb{R}$ is the constraint set of the interface tension $p^t_k$ corresponding to the $k$th joints defined by

$$X_k (p^t_k) = \{0 \leq p^t_k \leq t_k\} = [0, \ t_k],$$  

(69)

for $k = 1, \ldots, N$.

Similar case may exist at the interface between 2 blocks, as shown in Figure 17. Suppose 2 forces $F_1$ and $F_2$ are applied to the 2 blocks at points $A_1$ and $A_2$, respectively. The tensile resistance exerted by the cemented interface $C^i_1/C^i_2$ may be transferred to the 2 joints $C^i_1$ and $C^i_2$. Namely, the tensile resistance is in opposite direction to the resultant force of the interface tensions $-p^t_1 n_1$ and $-p^t_2 n_2$ acting on points $C^i_1$ and $C^i_2$ of block $B_i$, respectively. We assume an additive tensile strength

$$t = t_1 + t_2.$$  

(70)
where \( t_1 \) and \( t_2 \) correspond to contributions by joints \( C_1^i \) and \( C_2^i \), respectively. A tensile-shearing ratio between the two is introduced

\[
k_i = \frac{t_1}{t_2} = \frac{|\rho^1_i|}{|\rho^2_i|}
\]

(71)

to facilitate their individual contribution can be appropriately specified. The 2 joints, ie, \( C_1^i \) and \( C_2^i \), which belong to the same cementing interface, are called “adjoint joints” in this study. Hence, for a pair of adjoint joints, the condition in Equation (63) becomes

\[
\begin{aligned}
g_1^i &= \bar{g}_1^i - d_0^i \quad \text{if } p_1^i = 0 \\
g_2^i &= \bar{g}_2^i - d_0^i \quad \text{if } 0 \leq p_2^i \leq t_1 \\
g_1^i &= \bar{g}_1^i - d_0^i \quad \text{if } p_1^i = 0 \\
g_2^i &= \bar{g}_2^i - d_0^i \quad \text{if } 0 \leq p_2^i \leq t_2,
\end{aligned}
\]

(72)

where

\[
t_1 = \frac{k_1}{1 + k_1}, \quad t_2 = \frac{1}{1 + k_1}.
\]

(73)

5 | CONNECTOR

In a discrete particle/block system, any 2 independent particles or blocks can be connected through one or more connectors. The connectors considered in this study include rock bolts, springs, and beams.

5.1 | Rock bolt connector

The rock bolt is an effective reinforcement in civil and mining engineering. The original DDA is capable of simulating the behavior of rock bolt. Figure 18 shows 2 blocks \( B_1 \) and \( B_2 \) connected by a rock bolt \( A_1A_2 \), where points \( A_1(x_1, y_1) \) and \( A_2(x_2, y_2) \) are the 2 connecting points and forces \( F_1 \) and \( F_2 \) are the 2 axial forces acting on points \( A_1 \) and \( A_2 \), respectively. According to the original DDA without considering the bolt, the governing equation of the 2 blocks can be expressed as

\[
\begin{bmatrix}
K_{ij} & K_{ij} \\
K_{ji} & K_{jj}
\end{bmatrix}
\begin{bmatrix}
d_i \\
d_j
\end{bmatrix}
= \begin{bmatrix}
f_i \\
f_j
\end{bmatrix}
\]

(74)

where \( K_{ii} \) and \( K_{jj} \) are the equivalent stiffness matrices, the basic unknown vectors, and the equivalent loading vectors corresponding to blocks \( B_i \) and \( B_j \), respectively. Meanwhile, the link element in the theory of FEM presents the following form:

\[
\begin{bmatrix}
k_{1,1}^{Le} & k_{1,2}^{Le} \\
k_{2,1}^{Le} & k_{2,2}^{Le}
\end{bmatrix}
\begin{bmatrix}
u_1 \\
u_2
\end{bmatrix}
= \begin{bmatrix}
F_1 \\
F_2
\end{bmatrix}
\]

(75)

where \( u_1 \) and \( u_2 \) are the displacements of points \( A_1 \) and \( A_2 \), respectively, and

\[
k_{1,1}^{Le} = \frac{EA}{l}L, \quad k_{1,2}^{Le} = \frac{EA}{l}L, \quad k_{2,1}^{Le} = -\frac{EA}{l}L, \quad k_{2,2}^{Le} = \frac{EA}{l}L.
\]

(76)
where $E$, $A$, and $l$ are Young’s modulus, the cross-sectional area, and the length of the link element, respectively.

Substituting Equation (79) into Equation (75) and multiplying it by the transformation matrix $T_{ij}$ yields

$$E A \frac{l_i}{l} \begin{bmatrix} l_x & l_y \end{bmatrix} T_{ij} \rightarrow K_{ii},$$

$$- E A \frac{l_j}{l} \begin{bmatrix} l_x & l_y \end{bmatrix} T_{ij} \rightarrow K_{ii},$$

$$- E A \frac{l_j}{l} \begin{bmatrix} l_x & l_y \end{bmatrix} T_{ij} \rightarrow K_{ii},$$

and

$$\begin{bmatrix} T^T_{ij} & 0 \\ 0 & T^T_{ij} \end{bmatrix} \begin{bmatrix} F_1 \\ F_2 \end{bmatrix} \rightarrow \begin{bmatrix} f_i \\ f_j \end{bmatrix}.$$

By comparison, it is evident that the formulations in Equations (80) to (84) are indeed identical with their counterparts in the original DDA.\textsuperscript{31} In other words, because the principle of minimum potential energy is employed by DDA and FEM, we can use the simple transformation matrices and the relevant formulas (Equation (75) for link/bolt element, Equation (85) for spring element, and Equation (87) for beam element) in FEM to establish the controlling equation with considering rock bolt, spring (see Section 5.2), or beam (see Section 5.3).

5.2 Spring connector

Figure 19 shows 2 blocks $B_i$ and $B_j$ connected by a spring $A_1 A_2$. Points $A_1(x_1, y_1)$ and $A_2(x_2, y_2)$ are the 2 connecting points. Its FEM formula reads

$$\begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} F_1 \\ F_2 \end{bmatrix}.$$
In the same fashion as in Section 5.1 for rock bolt, one can obtain

\[ k \mathbf{T}_i^T \mathbf{T}_i \rightarrow \mathbf{K}_{i,i} \]
\[ -k \mathbf{T}_i^T \mathbf{T}_j \rightarrow \mathbf{K}_{i,j} \]
\[ -k \mathbf{T}_j^T \mathbf{T}_i \rightarrow \mathbf{K}_{j,i} \]
\[ k \mathbf{T}_j^T \mathbf{T}_j \rightarrow \mathbf{K}_{j,j} \]
\[ \mathbf{T}_i^T \mathbf{F}_1 \rightarrow \mathbf{f}_i \]
\[ \mathbf{T}_j^T \mathbf{F}_2 \rightarrow \mathbf{f}_j, \]

where \( k \) is the stiffness of spring.

### 5.3 Beam connector

Now, let us consider 2 particles \( P_i \) and \( P_j \) bonded together by an elastic beam AB, as shown in Figure 20. Points \( A(x_A, y_A) \) and \( B(x_B, y_B) \) are the 2 end points of the beam. There is an angle \( \theta \) between the local coordinate system \( \xi - \eta \) and the global coordinate system \( x-y \). The governing equation of the 2 particles without considering the beam is the same as Equation (73). According to the theory of beam element in FEM, the governing equation in the global coordinate system reads

\[
\begin{bmatrix}
k_{1,1}^{\text{Be}} & k_{1,2}^{\text{Be}} & k_{1,3}^{\text{Be}} & k_{1,4}^{\text{Be}} \\
k_{2,1}^{\text{Be}} & k_{2,2}^{\text{Be}} & k_{2,3}^{\text{Be}} & k_{2,4}^{\text{Be}} \\
k_{3,1}^{\text{Be}} & k_{3,2}^{\text{Be}} & k_{3,3}^{\text{Be}} & k_{3,4}^{\text{Be}} \\
k_{4,1}^{\text{Be}} & k_{4,2}^{\text{Be}} & k_{4,3}^{\text{Be}} & k_{4,4}^{\text{Be}}
\end{bmatrix}
\begin{bmatrix}
u_A \\
\theta_A \\
\nu_B \\
\theta_B
\end{bmatrix}
= \begin{bmatrix}
F_A^A \\
M_A^A \\
F_B^B \\
M_B^B
\end{bmatrix}.
\]

\[(87)\]
where \([u^A, \theta^A, u^B, \theta^B]^T\) is the degree of freedom of beam, \([F^A, M^A, F^B, M^B]^T\) is equivalent loading vector, and

\[
k_{Be}^{1,1} = \begin{bmatrix}
A_1 a^2 + A_2 b^2 & (A_1 - A_2) a \beta \\
(A_1 - A_2) a \beta & A_1 b^2 + A_2 a^2 
\end{bmatrix},
k_{Be}^{1,2} = \begin{bmatrix}
A_2 \beta \\
-A_1 a^2 - A_2 b^2
\end{bmatrix},
k_{Be}^{1,3} = \begin{bmatrix}
-A_1 a^2 - A_2 b^2 \\
(A_1 - A_2) a \beta
\end{bmatrix},
k_{Be}^{1,4} = \begin{bmatrix}
(A_2 - A_1) a \beta & A_3 \beta \\
-A_1 b^2 - A_2 a^2 & -A_3 a
\end{bmatrix}
\]

\[
k_{Be}^{2,1} = (k_{Be}^{1,1})^T, \quad k_{Be}^{2,2} = [A_4], \quad k_{Be}^{2,3} = [-A_3 \beta], \quad k_{Be}^{2,4} = [A_3 a \ A_5]
\]

\[
k_{Be}^{3,1} = (k_{Be}^{1,1})^T, \quad k_{Be}^{3,2} = (k_{Be}^{2,1})^T, \quad k_{Be}^{3,3} = [A_1 a^2 + A_2 b^2], \quad k_{Be}^{3,4} = [(A_1 - A_2) a \beta - A_3 \beta]
\]

\[
k_{Be}^{4,1} = (k_{Be}^{1,1})^T, \quad k_{Be}^{4,2} = (k_{Be}^{2,1})^T, \quad k_{Be}^{4,3} = (k_{Be}^{3,1})^T, \quad k_{Be}^{4,4} = \begin{bmatrix}
A_1 b^2 + A_2 a^2 & A_3 a \\
A_3 a & A_4
\end{bmatrix}
\]

\[
A_1 = \frac{E A}{l}, \quad A_2 = \frac{12 EI}{(1 + b) l^3}, \quad A_3 = \frac{6 EI}{(1 + b) l^2}, \quad A_4 = \frac{(4 + b) EI}{(1 + b) l}, \quad A_5 = \frac{(2 - b) EI}{(1 + b) l}
\]

\[
b = \frac{12 k_{Be} E (r \theta)^2}{G}, \quad \alpha = \cos \theta, \quad \beta = \sin \theta,
\]

where \(E, G, A, r, l, \) and \(I\) are Young's modulus, the shear modulus, the area of cross-section, the radius of gyration of cross-section, the length of the beam, and the bending stiffness of section, respectively. For the rectangular cross-section, \(k_{Be} = 1.2; \) while for the circular cross-section, \(k_{Be} = 10/9.\)

To establish the governing equation considering the beam, we introduce the following matrix:

\[
T_{ij}^{Be} = \begin{bmatrix}
T_{ij}^1 & 0 \\
E_{ij} & 0 \\
0 & T_{ij}
\end{bmatrix}
\]

(90)

For a rigid particle or block, \(E = [0 \ 0 \ 1];\) for a deformable particle, \(E = [0 \ 0 \ 0];\) and for a deformable block, \(E = [0 \ 0 \ 0 \ 0].\) Using the matrix \(T_{ij}^{Be}\), we can translate the degrees of freedom of the beam into the basic unknown vector of a particle or block, according to

\[
\begin{bmatrix}
u^A \\
\theta^A \\
u^B \\
\theta^B
\end{bmatrix} = \begin{bmatrix}
T_{ij}^1 & 0 \\
E_{ij} & 0 \\
0 & T_{ij}
\end{bmatrix} \begin{bmatrix}
d_i \\
0 \\
0 \\
d_j
\end{bmatrix}
\]

(91)

The substitution of Equation (91) into Equation (87) and premultiplying by \([T_{ij}^{Be}]^T\) gives

\[
T_{ij}^{T} \ k_{Be}^{1,1} T_{ij} + E_{ij}^{T} k_{Be}^{2,2} E_{ij} + \gamma_{ij}^{T} k_{Be}^{3,3} \gamma_{ij} + T_{ij}^{T} k_{Be}^{4,4} T_{ij} \rightarrow K_{ij}
\]

(92)

\[
T_{ij}^{T} F^A + E_{ij}^{T} M^A \rightarrow f_i
\]

\[
T_{ij}^{T} F^B + E_{ij}^{T} M^B \rightarrow f_j
\]

6 | COMPOSITE CONTACT MATRIX

6.1 | Node-based composite contact matrix

When a block needs to be subdivided into subelements to enhance the accuracy of strain or stress, this can be done by coupling the FEM with DDA. Consider a block B consisting of a total of \(3\)-node triangular elements, namely, \(E_1, E_2, \ldots, E_n\), with a total of \(n\) nodes. Force \(F\) is the prescribed external loading, and \(p_1, p_2, \ldots, p_m\) are the unknown contact forces acting on the boundary of the block, as shown in Figure 21.

For an arbitrary point \(A(x, y)\) in a 3-node triangular finite element \(E_k\), as shown in Figure 22, the interpolation shape function is given by

\[
\Delta T(x, y) = [\Delta T_n, \Delta T_n, \Delta T_n].
\]

(93)
\[ \Delta \mathbf{T}_i(x, y) = \begin{bmatrix} \phi_i & 0 \\ 0 & \phi_i \end{bmatrix}, \quad i = n_1, n_2, n_3, \]  

(94)

where \( \phi_i \) are the 3 area coordinates of point \( A(x, y) \); and \( n_1, n_2, \) and \( n_3 \) are the global indexes of the nodes with respect to block B (one can refer to the work of Fan et al. for more detail). In FEM, the basic unknown is the nodal displacement; the governing equation of motion of the block is expressed as

\[ \bar{K}\bar{d} - \mathbf{C^{Node}}\bar{p} = \bar{f}, \]  

(95)

where \( \bar{K} \) is the \( 2n \times 2n \) equivalent stiffness matrix and \( \bar{f} \) is the \( 2n \) equivalent nodal loading vector. The equivalent nodal displacement vector \( \bar{d} \) is

\[ \bar{d} = [u_1, v_1, \ldots, u_i, v_i, \ldots, u_n, v_n]^T, \]  

(96)

where \([u_i, v_i]^T\) is the displacement of \( i \)th node and the undetermined contact force vector \( \bar{p} \) reads

\[ \bar{p} = [p_1^n, p_1^r, \ldots, p_m^n, p_m^r]^T. \]  

(97)

In Equation (95), the \( 2n \times 2m \) matrix \( \mathbf{C^{Node}} \) is called the node-based composite contact matrix, which is closely related to the \( n \) nodes of the \( l \) elements and the \( m \) contact forces.

For any element \( E_k \) containing \( m_1 \)th to \( m_k \)th contact pairs \( (m_1, m_k) \) are the global indexes of contact forces with respect to the considered block B), we can construct the following triangular element contact matrix:

\[ \Delta \mathbf{C} = [\Delta \mathbf{C}_{m_1}, \ldots, \Delta \mathbf{C}_{m_j}, \ldots, \Delta \mathbf{C}_{m_k}], \]  

(98)

where each \( \Delta \mathbf{C}_{m_j} \) is the \( 6 \times 2 \) matrix associated with the \( j \)th contact point on element \( E_k \), and it can be written as

\[ \Delta \mathbf{C}_{m_j}(x_j, y_j) = s_j \Delta \mathbf{T}_j(x_j, y_j)[n_j, \tau_j], \quad j = m_1, \ldots, m_k, \]  

(99)

where \((x_j, y_j)\) is the coordinate of the \( j \)th contact point. The sign \( s_j \) and matrix \([n_j, \tau_j]\) are the same as the one in Equation (10).

Substitution of Equation (93) into Equation (99) yields

\[ \Delta \mathbf{C}_{m_j}(x_j, y_j) = s_j \Delta \mathbf{T}_{n_1} \Delta \mathbf{T}_{n_2} \Delta \mathbf{T}_{n_3}^T[n_j, \tau_j], \quad j = m_1, \ldots, m_k. \]  

(100)
Thus, we have

$$\Delta C_{i,j}(x_i, y_j) = s_j \Delta T_i(x_i, y_j) |n_i, r_j|, \quad i = n_1, n_2, n_3; \quad j = m_1, \ldots, m_k. \quad (101)$$

Up to now, the node-based composite contact matrix can be defined as

$$C_{\text{Node}}^{\Delta} = \begin{bmatrix} \Delta C_{1,1} & \Delta C_{1,2} & \cdots & \Delta C_{1,n} \\ \Delta C_{2,1} & \Delta C_{2,2} & \cdots & \Delta C_{2,n} \\ \vdots & \vdots & \ddots & \vdots \\ \Delta C_{n,1} & \Delta C_{n,2} & \cdots & \Delta C_{n,n} \end{bmatrix}, \quad i = 1, \ldots, n; \quad j = 1, \ldots, m, \quad (102)$$

where each of the $2 \times 2$ submatrix $\Delta C_{i,j}(i = n_1, n_2, n_3; \quad j = m_1, \ldots, m_k)$ is determined by Equation (101). Because $i = n_1, n_2, n_3$, and $j = m_1, \ldots, m_k$ are all the global indexes with respect to block $B$; therefore, the subscripts $i$ and $j$ are exactly the row index and the column index of $\Delta C_{i,j}$ in $C_{\text{Node}}^{\Delta}$.

To calculate the normal and shear contact gap pertaining to the contact point in a certain element $E_k$, it is necessary to obtain the nodal displacement vector $\mathbf{d}_k'$ and the flexibility matrix $F_k$ for the element $E_k$. For a noncontact step, from Equation (95), we have

$$\bar{\mathbf{d}}' = \mathbf{K}^{-1} \bar{\mathbf{f}}. \quad (103)$$

The nodal displacement vector $\mathbf{d}_k'$ of element $E_k$ can be obtained through

$$\mathbf{d}_k' = \begin{bmatrix} \bar{\mathbf{d}}'[2n_1 - 1 : 2n_1] \\ \bar{\mathbf{d}}'[2n_2 - 1 : 2n_2] \\ \bar{\mathbf{d}}'[2n_3 - 1 : 2n_3] \end{bmatrix}, \quad (104)$$

where $\bar{\mathbf{d}}'[2i - 1 : 2i](i = n_1, n_2, n_3)$ imply the elements of $\bar{\mathbf{d}}'$ from $(2i-1)$th to $(2i)$th. Moreover, $n_1$, $n_2$, and $n_3$ are the global indexes of the nodes. While the flexibility matrix $F_k$ of element $E_k$ is given by

$$F_k = \begin{bmatrix} \mathbf{K}^{-1}[2n_1 - 1 : 2n_1, :] \\ \mathbf{K}^{-1}[2n_2 - 1 : 2n_2, :] \\ \mathbf{K}^{-1}[2n_3 - 1 : 2n_3, :] \end{bmatrix} C_{\text{Node}}^{\Delta}, \quad (105)$$

where $\mathbf{K}^{-1}[2i - 1 : 2i, :]$(i = n_1, n_2, n_3) denote all column elements from $(2i-1)$th to $(2i)$th row of $\mathbf{K}^{-1}$ and $n_1$, $n_2$, and $n_3$ are also the global indexes of the nodes. Here, note that the “double contact displacement” should be adopted as well to avoid the “one-step lag.”

### 6.2 Particle/block-based composite contact matrix

Some particles or blocks can be connected by bolts, springs, or beams to build up an assembly, as shown in Figure 23. Assume that the total number of particles and blocks is $n$, namely, $B_1, B_2, \ldots, B_n$, the force $\mathbf{F}$ is the prescribed external loading, and $\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_m$ are the unknown contact forces acting on the assembly. The governing equation is

$$\bar{\mathbf{k}} \bar{\mathbf{d}} - C_p^{p/b} \bar{\mathbf{p}} = \bar{\mathbf{f}}, \quad (106)$$

where $\bar{\mathbf{k}}$ is the equivalent stiffness matrix and $\bar{\mathbf{f}}$ is the equivalent loading vector. The equivalent basic known vector $\bar{\mathbf{d}}$ is

$$\bar{\mathbf{d}} = [\mathbf{d}_1, \ldots, \mathbf{d}_i, \ldots, \mathbf{d}_n]^T, \quad (107)$$

where $\mathbf{d}_i$ corresponds to the $i$th particle or block $B_i$. The undetermined contact force vector $\bar{\mathbf{p}}$ is

$$\bar{\mathbf{p}} = \begin{bmatrix} \mathbf{p}_1^T, \mathbf{p}_i^T, \ldots, \mathbf{p}_m^T \end{bmatrix}^T. \quad (108)$$

In Equation (106), the matrix $C_p^{p/b}$ is called the particle/block-based composite contact matrix, which is given by

$$C_p^{p/b} = \begin{bmatrix} C_1 \\ \vdots \\ C_i \\ \vdots \\ C_n \end{bmatrix}, \quad i = 1, \ldots, n, \quad (109)$$
where \( C_i \) is the contact matrix for the particle or block and is determined by Equation (9).

To estimate the normal or shear contact gap for a contact point pertaining to a certain particle or block \( B_i \), we have to solve the known vector \( \tilde{d}^f \) and the flexibility matrix \( \tilde{F}_i \) for block \( B_i \). For the noncontact step, from Equation (106), we have

\[
\tilde{d}^f = \tilde{K}^{-1} \tilde{f},
\]

and

\[
\tilde{d}^f_i = \left[ \tilde{d}^f [k_0(i-1)+1 : k_0i] \right],
\]

where \( \tilde{d}^f[k_0(i-1)+1 : k_0i](i = 1, \ldots, n) \) stand for the elements of \( \tilde{d}^f \) from \( k_0(i-1) \)th to \( k_0i \)th. For an assembly consisting of rigid particles and blocks only, \( k_0 = 3 \); for one with deformable particles, \( k_0 = 4 \); and \( k_0 = 6 \) for an assembly comprised of deformable blocks. The flexibility matrix \( \tilde{F}_i \) of block \( B_i \) is

\[
\tilde{F}_i = \left[ \tilde{K}^{-1} [k_0(i-1)+1 : k_0i, :] \right] C_{P/b}^i, \quad i = 1, \ldots, n,
\]

where \( \tilde{K}^{-1} [k(i-1)+1 : k_i, :] \) signify all column elements from \( k_0(i-1) \)th to \( k_0i \)th row of \( \tilde{K}^{-1} \). Then, the compatibility iteration is employed to solve the unknown contact forces.

If there are \( m \) rolling resistances, the following particle/block-based composite rolling resistance matrix \( R_{P/b}^i \) should be used:

\[
R_{P/b}^i = \begin{bmatrix}
R_1 \\
\vdots \\
R_i \\
\vdots \\
R_m
\end{bmatrix}, \quad i = 1, \ldots, m,
\]

where \( R_i(i = 1, \ldots, m) \) is determined by Equation (50). To form the corresponding equivalent rolling resistance vector, Equations (47), (49), and (59) can be used.

7 | NUMERICAL EXAMPLES

In this section, several interesting and challenging examples are designed to validate the potential of the new DDA. For convenience, DDA denotes the original DDA for an arbitrary shape block with first-order displacement field. D-DDA refers to the DDA with rigid disks only. DDA-d stands for the modified DDA described in the work of Zheng et al., while PB-DDA stands for the proposed DDA in this study. In the following examples, an extremely large density is adopted for a static particle or block to avoid the introduction of additional energy caused by the usage of fixed springs.

7.1 | Static heap of 3 disks

The first problem to be considered is a static heap formed by 3 disks, as shown in Figure 24. Three rigid disks of the same size are placed over one another vertically on a fixed horizontal base before the gravity is switched on. The weights of the 3 disks are \( G_1, G_2, \) and \( G_3 \), respectively. An idealized configuration is employed to test the proposed algorithm. Let the radius of all 3 disks \( R = 10.0 \) m and their material density is the same \( \rho = 2500 \text{ kg/m}^3 \). Assume the acceleration of
gravity \( g = -10 \) m/s\(^2\). An extremely large density \( \rho_b = 10^{11} \rho \) is assumed for the base to render it stationary. A time step length \( \Delta = 0.001 \) s is adopted. A zero-order displacement approximation is adopted in the PB-DDA. In the following simulations, several penalty parameters \( P = 0.10 \times 10^{12}, 0.10 \times 10^{13}, 0.10 \times 10^{14}, \) and \( 0.10 \times 10^{15} \) Pa are used by the D-DDA to observe the stability of the 3 disks. If the system is stable, it is evident that contact forces \( F_1 = G_1, F_2 = G_1 + G_2, \) and \( F_3 = G_1 + G_2 + G_3, \) respectively. Some representative values for contact forces obtained from the D-DDA and PB-DDA are listed in Table 1. Evidently, the absolute errors of contact forces obtained by D-DDA do not show a consistent negative correlation with the penalty value since, when the penalty number is increased to \( P = 0.10 \times 10^{15} \) Pa, the absolute errors blow up again. However, since no contact penalty is needed in PB-DDA, the absolute accuracy is improved almost one order of magnitude compared with the best case by D-DDA (\( P = 0.10 \times 10^{14} \) Pa).

### 7.2 Static stability of 4 blocks

A second example to be considered is the static stability of 4 identical blocks \( B_1, B_2, B_3, \) and \( B_4 \) stacked, as shown in Figure 25, on a static horizontal base. The length and width of the blocks are 20.0 m, and 10.0 m, respectively. The staggering distance is 5.0 m. The gravity is the only external force loaded on them. The forces \( F_1 \) and \( F_2 \) are the contact forces acting on block \( B_4 \) at points \( A_1 \) and \( A_2, \) respectively. Under the given geometric conditions and statics relation with positive contact forces \( F_1 \) and \( F_2, \) the 4 blocks are theoretically stable. The material density of the blocks is \( \rho = 2000 \) kg/m\(^3\). The acceleration of gravity is set \( g = -10 \) m/s\(^2\), and the time step \( \Delta = 0.001 \) second. To avoid the motion of base, a big material density is given for the base at \( \rho_b = 10^{11} \rho, \) and its weight is ignored. The computations of DDA\(_0\), and PB-DDA adopt Young’s modulus \( E = 0.10 \times 10^{15} \) Pa and Poisson’s ratio \( \nu = 0.45. \) In this example, 4 cases of penalty parameters \( P = 0.10 \times 10^{12}, 0.10 \times 10^{13}, 0.20 \times 10^{14}, \) and \( 0.10 \times 10^{15} \) Pa are considered in the DDA\(_0\). Table 2 summarizes typical contact forces \( F_1 \) and \( F_2 \) obtained by the 2 approaches. When \( P = 0.10 \times 10^{12} \) Pa, the calculations by DDA\(_0\) suggest that the 4 blocks are stable, but the obtained contact forces indicate otherwise. When \( P \geq 0.10 \times 10^{13} \) Pa, the values of the contact forces obtained by DDA\(_0\) are consistent with its analysis result. There is no apparent correlation between the penalty

---

7.3 Reciprocal motion of a ring particle within a frame

In this example, we consider the undulation motion of a ring particle in a frame to examine the “one-step lag” phenomenon and the effectiveness of its treatment by the “double contact displacement” approach. Suppose the inner and external diameters of the ring particle are 2.0 m and 6.0 m, respectively. At initial time, the ring particle is located at the centroid of a quadrature frame (the inner side length is equal to 40.0 m), which is kept static. Moreover, the initial velocity of the ring particle is set as $v = (2.5, 5.0) \text{ m/s}$. Both the particle and the frame are assumed to be rigid bodies. Neither external force nor friction is considered. Due to the conservation of momentum, the ring particle will undergo reciprocal motion along the blue dash line, as shown in Figure 26, along which there are 6 inflection points marked by “*.” The time step is chosen as $\Delta = 0.05$ second, and the total calculation step is $CS = 2050$. The predictions are shown in Figure 27.

In designing the example in Figure 26, we specifically assume that both components of the initial velocity are nonzero and demonstrate the “one-step lag” prediction by DDA-d. This makes the displacement in the normal direction remain

</table>

Note: Analytical solution (N): $F_1 = 1 000 000.00000$; $F_2 = 7 000 000.00000$. Abbreviations: AE, absolute error; CS, calculation step; DDA, discontinuous deformation analysis; PB-DDA, particle-block discontinuous deformation analysis.
always one time step behind the displacement in the shear direction. The trajectory (the red solid line in Figure 27A) of the particle predicted by the DDA-d shows apparent deviations from the theoretical trajectory (the blue dash line in Figure 27A). On the other hand, the PB-DDA improved by the “double contact displacement” technique can provide nearly identical predictions with the theoretical solution, as shown in Figure 27B.

### 7.4 Cyclic motion of a block

A third case treated here is the cyclic motion of a block within a static quadrate framework, as shown in Figure 28, to validate the conservation of momentum. The internal side length of the quadrate framework is 120.0 m, while the side length of the block is 20.0 m. At the initial time, the centroid of the block coincides with that of the framework, i.e., point O. The initial velocity of the block is given by \( \mathbf{v} = (2.5, 5.0) \) m/s (denoting horizontal and vertical components of the velocity, respectively). No external local is considered in this example. Due to the conservation of momentum, the block will undergo periodical translational motion along the blue dash line, along which there are 6 inflection points marked by “*.” For both the block and the framework, Young’s modulus \( E = 0.50 \times 10^{14} \) Pa and Poisson’s ratio \( \nu = 0.35 \) are adopted. The material density of block is set to \( \rho = 2300 \) kg/m\(^3\) and that of the framework to \( \rho_f = 10^9 \rho \). The framework is assumed to be motionless. The time step is \( \Delta t = 0.01 \) second. Five sets of penalty parameters are adopted by the DDA\(_0\), i.e., \( P = 0.10 \times 10^{12}, 0.10 \times 10^{13}, 0.10 \times 10^{14}, 0.10 \times 10^{15}, \) and \( 0.10 \times 10^{16} \) Pa. The trajectory of point O is shown in Figure 29.

Notably, the predictions by DDA\(_0\) and PB-DDA are different. When \( P = 0.10 \times 10^{12} \), only the first segment AB of the trajectory (the red solid line) for point O predicted by DDA\(_0\) is correct (see Figure 29A). While for the other 4 cases of penalty parameters, only the initial segments ABCD of the trajectory of point O predicted by DDA\(_0\) coincide with the theoretical trajectory (the blue dash line), and apparent block rotation is found in all 4 cases (see Figure 29B, 29C, 29D, and 29E). In contrast, the predicted trajectory of point O by PB-DDA agrees well with the theoretical trajectory, and the

---

**FIGURE 27** Reciprocating motion of a particle. A, Prediction by DDA-d; B, Prediction by PB-DDA

**FIGURE 28** Configuration of a block in a quadrate framework
FIGURE 29  Trajectories of point O predicted by DDA₀ in A, B, C, D, and E and by PB-DDA in F. A, \( P = 0.1 \times 10^{12} \) Pa, CS = 10 000; B, \( P = 0.1 \times 10^{13} \) Pa, CS = 10 000; C, \( P = 0.1 \times 10^{14} \) Pa, CS = 10 000; D, \( P = 0.1 \times 10^{15} \) Pa, CS = 10 000; E, \( P = 0.1 \times 10^{16} \) Pa, CS = 10 000; F, \( P \) is not needed, CS = 10 000

block undergoes translational motion only, as shown in Figure 29F. Indeed, since DDA₀ does not refer to the acceptable contact force, the conservation of momentum is satisfied only at the initial stages corresponding to segments ABCD of the trajectory. Therefore, the trajectory of the block may not be faithfully predicted, especially for later stage of the simulation. In particular, it is also difficult to determine an appropriate penalty parameter for DDA₀ in such cases. The PB-DDA clearly helps us avoid this issue.

7.5  Rolling of a disk on a frictionless surface inside a ring

Figure 30 presents a disk \( O₁ \) is initially located inside a ring \( O₂ \) at point A (−60.0, 0.0) where points A, \( O₁ \), and \( O₂ \) are on the same horizontal line \( AO₁O₂ \). The radii of the disk and the inner ring are given by \( R₁ = 40.0 \) m and \( R₂ = 100.0 \) m, respectively. The material density of the disk \( \rho = 1 \) kg/m³, and the material density of ring adopts an extreme value of \( \rho = 10^{12} \rho \) to prevent the motion of ring. Gravity and friction are not considered for the ring. The acceleration of gravity \( g = -10 \) m/s². Both the disk and the ring are assumed to be rigid. The time step is set to \( \Delta = 0.005 \) second, and the total calculation step CS = 4 000. Under gravity, the disk will move periodically along the bottom half circle of the ring, with a theoretical curve of contact force depicted in Figure 31. During the first semiperiod at the time \( t₁ = 4.675 \) seconds, the maximum contact force predicted by PB-DDA is \( F_{\text{max1}} = 150803.493116 \) N, which agrees well with the theoretical solution \( F = 3 \ mg = 150796.447372 \) N. During the second semiperiod at the time \( t₂ = 14.025 \) seconds, the maximum contact force is \( F_{\text{max2}} = 150796.553208 \) N, which is almost identical with the theoretical solution \( F = 3 \ mg = 150796.447372 \) N. The
FIGURE 30 Configuration of a disk in a ring [Colour figure can be viewed at wileyonlinelibrary.com]

predicted trajectory of point $O_1$ by PB-DDA is shown in Figure 32. It is observed that the disk may climb up to the same height at point $O_1^*$ on the right-hand side as its releasing point $O_1$, and then go back to point $O_1$ again, which implies both the mechanical energy and the moment of the system are conservative by the proposed algorithm.

7.6 Sliding motion of a block on frictional surface

A further example of block with a side length of $l = 1.0$ m sliding on friction surface of a static block is investigated, as shown in Figure 33. Contacts $V_1$-BC-$BB$ and $V_2$-BC-$BB$ are the pairs of adjoint vertex-edge contacts. $G$ is the gravity. A given tractive force $F = 1000$ N is applied to point $A$. The contact forces $F_{n1}$, $F_{s1}$, $F_{n2}$, and $F_{s2}$ are undetermined. Both blocks are assumed to be rigid body. For the smaller block, the material density is specified at $\hat{\rho}_1 D = 1000 \text{ kg/m}^3$, and the acceleration of gravity $g = -10 \text{ m/s}^2$. For the bigger block, the material density of block is given by $\hat{\rho}_2 = 10^{12} \hat{\rho}_1$. The time step is set to be $\Delta = 0.01$ second. In order to examine the relative motions between the 2 contact pairs, we set the eccentric distance $d = 0.7$ m, the sliding friction coefficient $\mu = 0.0$, and the cohesion $c = 400$ N. The predicted results are shown in Table 3. In DDA-d, because the shear ratio between the adjoint vertex-edge contacts is ignored, the over-resistance to the sliding arises, which leads to incorrect predictions of the normal and shear contact forces by DDA-d. In contrast, the contact forces predicted by the PB-DDA agree rather well with the theoretical solutions.
7.7 Rolling motion of a disk on frictional surface

In this example, we consider the rolling motion of a disk of $R = 1.0$ m over the frictional surface of a static block, as shown in Figure 34. Points A and O are taken as 2 monitoring points. The material density of the disk is set to be $\rho = 1000$ kg/m$^3$ and the acceleration of gravity $g = -10$ m/s$^2$. In PB-DDA, the disk is treated as a rigid body, while the block is assumed deformable, and its gravity is not considered. The material density of block is given by $\rho_b = 10^{12}$ kg/m$^3$; its Young’s modulus is set to $E = 0.10 \times 10^{10}$ Pa and its Poisson’s ratio $\nu = 0.25$. The time step is set to be $\Delta = 0.01$ second. Under the gravity $G$, a given tractive force $F = 1000$ N, and the unknown contact force, the disk will move rightwards. Several cases of distance $d = 0.0, 0.5, 1.0, 1.5, \text{ and } 2.0$ m between the line of action of the force $F$ are explored. The contact surface AB is adopted to test the pure rolling motion of the disk. The major results are summarized in Table 4. The predicted maximum normal contact force $F_n$ by the PB-DDA has an absolute error of 0.00182 N as compared with the theoretical value, while that for the shear contact force is 0.00001 N, showing rather accurate predictions by the PB-DDA.

Meanwhile, to examine the rolling resistance effect, a large rolling friction coefficient $\delta = 1.0$ m is adopted (which means that the range of value of rolling resistance moment is limited between $-1G$ and $1G$ while the disk remains static). The predicted results are summarized in Table 5. At difference distance $d$, PB-DDA realistically predicts appropriate rolling resistance moment in resisting the rolling motion of the disk. The displacements of points A and O, namely, $U_A$ and $U_O$, are predicted to be zero, implying no move for the 2 points as expected.
To investigate the motion of the disk, we further fix $d = 1.0$ m, and the total calculation step $CS = 500$, and consider the following 3 cases. (I) The sliding friction coefficient is specified at a large value at $\gamma = 10.0$ and the rolling friction coefficient $\delta = 0.0$ m, which renders the disk to undergo pure rolling. (II) The sliding friction coefficient is set at $\gamma = 0.005$ and the rolling friction coefficient at $\delta = 0.005$ m. The disk will undergo both sliding and rolling in this case. (III) The sliding friction coefficient is set at $\gamma = 0.005$ and the rolling friction coefficient at $\delta = 0.0$ m, whereby no rolling resistance is considered. The trajectories of points A and O are shown in Figure 35.

When $CS = 500$, points A and O reach points A* and O*, respectively (see Figure 35). For the pure rolling, namely, case I, the length of the blue trajectory OO* is the shortest, while the curvature of the blue trajectory AA* is the biggest. As can be seen, due to the decrease in sliding friction coefficient and increased rolling resistance, the red trajectory OO* in case III is the longest and the curvature of the red trajectory AA* is the smallest. For case II, the length of the green straight OO* and the curvature of the green curve AA* are in between cases I and III.

### 7.8 Two blocks connected by a cemented interface

Figure 36 shows 2 blocks $B_1$ and $B_2$ connected by a cemented interface $C_1C_2$, which is designed to validate the cemented interface model of our new PB-DDA. Lines AB and CD are the geometric symmetry lines of block $B_2$. The half-height of block $B_2$ is $H = 1.0$ m. As we proposed, the cemented interface $C_1C_2$ is made equivalent by 2 joints $C_1$ and $C_2$. The action point of force $F$ is on line CD and in parallel with line AB, with a vertical distance between the line of action of

F and line AB by \( h \). In our simulation, it is assumed that \( F = 1000 \) N, the material density of block \( B₂ \) \( \rho = 1000 \) kg/m\(^3\), and the gravity is ignored. Block \( B₁ \) is assumed to be fixed without motion. In addition, the 2 blocks are considered as nondeformable. The time step is set to 0.01 second; the tensile strength of cementing material is given by \( t = 2000 \) N. The interface tensile forces \( P₁ \) and \( P₂ \) are predicted when \( B₂ \) is subjected to \( F \), and the results are summarized in Table 6. Evidently, the numerical predictions by PB-DDA are rather close to the theoretical solutions.

7.9 Undulation motion of a circle particle

The bouncing motion of a particle between 2 static blocks, as shown in Figure 37, is taken as an example to examine the node-based composite contact matrix. A particle of radius \( r = 0.5 \) m is assumed to be initially located in between 2 blocks \( (H₁ = H₂ = 0.5 \) m\). Both blocks are supposed to be static, and the bottom block is subdivided into subelements. Both the upper block and the particle are treated as rigid bodies, while the bottom block with a Young’s modulus \( E = 0.10 \times 10^{15} \) Pa and a Poisson’s ratio \( \nu = 0.45 \). Therefore, its deformation can be ignored; this is appropriate for examining the node-based composite contact matrix. The material density of the particle \( \rho = 2500 \) kg/m\(^3\), and its gravity is ignored. The initial velocity of the particle is set to be \( V₀ = (v₀x, v₀y) = (v₀x = 1.0, v₀y = 1.0, 2.0, \) or \( 3.0) \) m/s. The time step is set to be 0.05 second, and the total time is equal to 1.0 second. Therefore, the particle will arrive to point B (the distance between points A
and B is $L = 1.0$ m) after several collisions, the times of which depends on the value $v_{0y}$. When $V_0 = (1.0, 1.0)$ m/s, the particle arrives at point B after going through 2 collisions, as shown in Figure 38A. The trajectory of centroid of particle resembles a single-period triangular wave. When $V_0 = (1.0, 2.0)$ m/s, 4 collisions are needed to allow the particle to reach B, and the 2-period triangular wave is accurately predicted by PB-DDA, as shown in Figure 38B. If $V_0 = (1.0, 3.0)$ m/s, the corresponding trajectory appears as the triangular wave with 3 periods, while the time of collisions is 6, as shown in Figure 38C. The example demonstrates that the principle of conservation of energy is strictly satisfied in the coupling of PB-DDA and FEM. This means that the node-based composition contact matrix is right and valid.
7.10 | Drop of a particle “chain”

Figure 39 further presents an example of particle “chain” to examine the validity of the particle/block-based composite contact matrix proposed by this study. A chain consisting of 2 star-shaped blocks and 9 smaller identical particles with a radius $r = 2.0$ m is considered, and springs are used to connect these particles/blocks. The particle “chain” is initially placed at a height of $H = 3.0$ m above a bigger static particle of radius $R = 8.0$ m. The gravity is then turned on for the “chain,” leading its fall and impact on the bottom bigger particle. The acceleration of gravity $g = -10$ m/s$^2$, and the time step is set to be $\Delta = 0.005$ second. All blocks and particles in the chain are assumed to be rigid bodies. The stiffness of

![Configuration of a particle “chain”](wileyonlinelibrary.com)

![Movement of a “chain” obtained by particle-block discontinuous deformation analysis.](wileyonlinelibrary.com)
the 10 springs is equal to $0.5 \times 10^{10}$ Pa. The 10 springs not only serve as the connectors but also play a role of energy absorbers. The dynamic behavior of the “chain” is examined. When CS = 155, the “chain” touches the bottom static particle, as shown in Figure 40A. While the middle part of the “chain” rebounds slightly, its 2 ends continue to move down accompanied by rotation, as shown in Figure 40B. At CS = 263, the 2 stars impact on the bigger particle, as shown in Figure 40C and then start to bounce back. Figure 40D shows the position of the “chain” at CS = 540. After a long time, due to the loss of kinetic energy, the “chain” settles down on the bigger particle, as shown in Figure 41.

From this example, we can safely conclude that the dynamic behavior of the “chain” can be captured by the governing equation with the particle/block-based composite contact matrix.

8 | CONCLUSIONS

A new comprehensive framework of DDA has been proposed to simulate discrete particle-block systems wherein rigid and nonrigid circle particles, ring-shaped particles, arbitrary-shaped block, and various complicated contact types among them have been rigorously integrated. The mechanics of rolling resistance and the tensile resistance at cemented inter-face have also been carefully considered, with their equivalent variational or quasivariational inequality formulations in conjunction with constraint conditions on the normal and shear contacts being incorporated into the framework. The following apparent benefits are gained through the new formulations of the DDA framework toward modeling a discrete particle-block system. (i) It helps get rid of the necessity of artificial springs in coping with potential interactions occurring between individual bodies, which, otherwise, are always needed in other DDA methods. (ii) The existing formulas governing the link, spring, and beam elements in FEM are exploited to establish the relevant controlling equations in PB-DDA using the simple transformation matrices, which help bypass complicated mathematical derivations. (iii) The node-based composite contact matrix derived for coupled modeling of PB-DDA and FEM may help enhance the accuracy of predicted stresses and strains. (iv) The particle/block-based composite contact matrix obtained in this study enables the proposed PB-DDA to retain all functions of the original DDA while broadening its application range. The accuracy and effectiveness of the proposed new DDA framework have been validated through a wide variety of demonstrated examples. Next, we will extend the proposed DDA framework to 3-dimensional cases and investigate the corresponding parallel algorithm.

APPENDIX

DERIVATION OF MATRICES GOVERNING RIGID OR DEFORMABLE CIRCLE OR RING PARTICLES

Take a deformable ring, as shown in Figure A1, as an example, where \( R_E \) and \( R_I \) are the external and inner diameters of the ring, respectively. The rectangular coordinate system \( X-Y \) is global, while the coordinate system \( x-y \) is the local coordinate system with taking the centroid \( C(X_c, Y_c) \) of the ring as the origin of coordinates. Note that \( x \)-axis is meanwhile the polar axis of local polar coordinates.

### A.1 | Submatrix of stiffness

The stiffness submatrix can be expressed in the following general form:

\[
K_p = \int \int B^T D B dX dY, \tag{A.1}
\]

where

\[
D = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \tag{A.2}
\]

and

\[
E = \frac{E}{1 - \nu^2} \begin{bmatrix} 1 & \nu \\ \nu & 1 \end{bmatrix}, \tag{A.3}
\]

where \( E \) and \( \nu \) are the Young’s modulus and Poisson’s ratio, respectively. In consideration of Equations (A.2) and (A.3), Equation (A.1) can be recast into

\[
K_p = \frac{\pi E (R_E^2 - R_I^2)}{1 - \nu} \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{A.4}
\]

### A.2 | Submatrix of mass

The mass submatrix can be generally written as

\[
M_p = \int \int T^T T dX dY, \tag{A.5}
\]

where \( T \) is the interpolation shape function. The relationship between the global coordinate system \( X-Y \) and the local coordinate system \( x-y \) reads

\[
\begin{align*}
X &= x + X_c \\
Y &= y + Y_c.
\end{align*} \tag{A.6}
\]

FIGURE A1  A deformable ring [Colour figure can be viewed at wileyonlinelibrary.com]
The relationship between the polar coordinates and the local rectangular coordinates is given by

\[ x = r \cos \theta \]
\[ y = r \sin \theta, \]

where \((r, \theta)\) is the polar coordinate of any point in ring. For an infinitesimal area \(dA\), we have

\[ dA = dx\,dy = rdrd\theta. \]

Using Equations (A.6) to (A.8) yields

\[
\mathbf{M}_F = \begin{bmatrix}
g_1 & 0 & 0 & 0 \\
0 & g_1 & 0 & 0 \\
0 & 0 & g_2 & 0 \\
0 & 0 & 0 & g_2
\end{bmatrix},
\]

(A.9)

where

\[
g_1 = \pi (R_E^2 - R_I^2), \quad g_2 = \pi (R_E^4 - R_I^4)/2.
\]

(A.10)

### A.3 Submatrix of initial stress

The initial stress submatrix generally presents the following form:

\[
\mathbf{f}_0 = \iint B^T \begin{bmatrix} \sigma_0 \\ \sigma_0 \end{bmatrix} dX\,dY,
\]

(A.11)

where \(\sigma_0\) is the initial stress. Substituting Equation (A.2) into Equation (A.11) leads to

\[
\mathbf{f}_0 = 2\pi (R_E^2 - R_I^2) \begin{bmatrix} 0 \\ 0 \\ 0 \\ \sigma_0 \end{bmatrix}.
\]

(A.12)

### A.4 Submatrix of body force

The body force submatrix is written as

\[
\mathbf{f}_{body} = \iint T^T \begin{bmatrix} f_X \\ f_Y \end{bmatrix} dX\,dY,
\]

(A.13)

where \(f_X\) and \(f_Y\) are 2 components of body force. Substituting Equation (A.2) into Equation (A.11) and considering Equations (A.7) and (A.8) yields

\[
\mathbf{f}_{body} = \pi (R_E^2 - R_I^2) \begin{bmatrix} f_X \\ f_Y \\ 0 \\ 0 \end{bmatrix}.
\]

(A.14)
